Protein And Carbohydrate: Strategies To Improve Piglet Diet Digestibility

o maintain a strong performance into the grow-out stage, young pigs require good nutrient intake from birth.

Often inadequate to sustain all piglets in the litter throughout lactation, sow's milk can be supplemented by creep feeding which helps stimulate the piglet's digestive enzymes. A good creep diet enables a smooth liquid-to-solid feed transition. Studies also show that exposing young animals to solid feed days before weaning creates more "eaters" (Sulabo et al 2010).

Poor digestion escalates the incidences

of diarrhea (Figure 1; a direct correlation between stool score and undigested nutrient in feces). Although creep diets should contain high amounts of energy and nutrients, limited enzyme activities in the gut cannot fully digest these nutrients. Undigested nutrients are acted upon by enteric bacteria through fermentation. Diarrhea occurs when the villi secretes water to eject the bacteria, toxins and undigested feeds.

Undigested nutrients in the ileal region triggers a feedback mechanism (ileal brake). The body interprets that the digesta would require more time to be digested; the ileal brake would slow its passage rate (Read et al., 1984: Spiller et al., 1984, 1988), thus hampering

Nutrient utilisation should be improved through a comprehensive strategy in gut health; a good understanding of nutrients in feed ingredients helps develop diets with better protein digestibility.

voluntary feed intake (Van Citters and Line. 1999)

Thus, diets require carefully selected ingredients and special formulation strategies to prevent enteric bacteria from feeding on undiaested nutrients.

Enhancing protein digestibility

A protein source's digestibility and quality influence gut health. Given the digesta's short

transit time along the piglet's gut, protein sources must be easily digested.

Undigested protein causes bacterial fermentation in the large intestine and the subsequent production of toxins metabolites, consequentially impacting the intestinal mucosa and shifting energy to ammonia excretion that could otherwise support growth. The insufficient gastric acid and protease activity give rise to undigested nutrients by the time the digesta reaches the hind gut. Cargill Animal Nutrition (CAN) addresses this issue with a nutrient called swine gut fermentable protein (SW_GUT_FP) when formulating piglet feed.

SW_GUT_FP exists in many ingredients (whey protein concentrate, 142%; fishmeal, 2.34%; and soybean meal, 3.66%]. Figure 2 shows that a high SW_GUT_FP resulted in poor stool quality in the first week and first 3 weeks post weaning compared to a low SW GUT FP diet. Toxic metabolites damaged the aut integrity resulting in poor stool quality.

Figure 2. Effect of high vs low SW GUT FP on stool quality.

Different protein sources based on villi characteristics can also affect piglet performance (the best protein source is milk - see Table 1).

Additionally, when considering protein plant sources, it is important to select

processed ingredients which are absent of impurities and anti-nutritional factors that affect the piglet's gut. CAN's findings show that hydrothermally extruded soybean promotes

Table 1. Protein sources and gut development.				
Parameter	Milk protein	Soybean meal	Soy protein concentrate	CAN Hydrothermally Extruded Soybean
Villi Height (µm)	364	234	309	319
Crypt depth (µm)	198	222	214	196
ADG 0-14d (g/d)	326	182	208	227
FCR	0.99	1.38	1.14	1.09

higher feed intake and higher growth rate in weaned piglets. CAN recommends improving nutrient utilisation through a comprehensive strategy in gut health; a good understanding of nutrients in feed ingredients (such as SW GUT FP) helps develop diets with better protein digestibility.

Enhancing carbohydrate digestibility

Piglets could digest lactose better than the starch component in carbohydrates. Initial creep diets should contain sufficient lactose, which can be lowered in phases. The pialet's diaestive system must be induced to develop amylase activity in saliva and the pancreas through gradual exposure to carbohydrate sources. To promote solid feed intake, highly digestible carbohydrate sources should be introduced in the feed until the piglet's digestive system develops fully.

CAN recommends that a significant amount of starch must be highly digestible. The feeding value would depend on the starch's structure, the starch's accessibility to enzymatic digestion and the processing or treatment of the cereal. Some resistant starch could be added to promote gut health.

For good lactose levels, highly digestible cereal should be included to improve the total starch digestibility. Thermo-mechanical treatment through extrusion will boost the cereal's starch digestibility. Another study (Carter et al., 1991) shows the effect of

Figure 1. Stool score and undigested nutrients

extrusion of wheat on in vivo digestibility (see Figure 3). The piglets were weaned at 14 days of age, where they were fed either raw or extruded wheat as the main energy source.

cases.

Digestibility measured at 45 days of age in different parts of the gut showed that starch digestibility was higher for "extruded wheat" than "raw wheat" in some areas.

> CAN's studies

Figure 3. Starch digestibility in different parts of the

showed cereals that underwent such

treatments had shorter digestion time, while

a higher feed intake was observed in these

An accurate understanding of nutrient values enables proper diets with fulfilled nutrient requirements and highly digestible ingredients. Supporting nutritional plans are ingredient and feed evaluation services which provide rapid ingredient analysis and precise feed formulation. Provimi's expertise in these fields enables more cost-effective feeding strategies which improve digestibility in piglet diets. 😚
